Received 13 August 2003; accepted in revised form 3 February 2004

Abstract

Litho-, bio-, and chemostratigraphy of the Cretaceous forearc basin sediments exposed in Hokkaido, northern Japan allow a synthesis of the faunal, sedimentological, and environmental history of the north-west Pacific margin. Although the succession, named the Yezo Group, has yielded an abundant record of mid- to late Cretaceous invertebrates, monotonous lithologies of sandstone and mudstone, showing occasional lateral facies changes, have caused confusion regarding the lithostratigraphic nomenclature. Based on our wide areal mapping of the sequence, and analysis of litho- and biofacies, a new lithostratigraphic scheme for the Yezo Group is proposed. In ascending order, the scheme is as follows: the Soashibetsugawa Formation (Lower Aptian mudstone unit); the Shuparogawa Formation (Lower Aptian—lower Upper Albian sandstone-dominant turbidite unit); the Maruyama Formation (lower Upper Albian tuffaceous sandstone unit); the Hikagenosawa Formation (Upper Albian—Middle Cenomanian mudstone-dominant unit); the Saku Formation (Middle Cenomanian—Upper Turonian sandstone-common turbidite unit); the Kashima Formation (Upper Turonian—Lower Campanian mudstone-dominant unit); and the Hakobuchi Formation (Lower Campanian—Paleocene shallow-marine sandstone-conglomerate unit). In addition, we designate two further lithostratigraphic units, the Mikasa Formation (Upper Albian—Turonian shallow-marine sandstone-dominated unit) and the Haborogawa Formation (Middle Turonian—Campanian shelf mudstone/sandstone unit), which correspond in age to the shallower facies of the Saku and Kashima formations, respectively.

Despite a lack of so-called “black shales”, because of siliciclastic dilution, our stratigraphic integration has revealed the horizons of oceanic anoxic events (OAEs) in the Yezo Group. The OAE1a horizon in the Soashibetsugawa Formation is characterized by a lack of foraminifers, macrofossils and bioturbation, and a prominent positive excursion of $\delta^{13}$C\textsubscript{org}. A significant hiatus during the late Aptian and early Albian removed the OAE1b horizon. The OAE1c horizon in the Maruyama Formation shows a distinct negative excursion of $\delta^{13}$C\textsubscript{org} with a concomitant high productivity of radiolarians. The OAE1d horizon in the middle part of the Hikagenosawa Formation consists of weakly laminated, pyrite-rich mudstone. Planktonic and calcareous benthic foraminifers are absent, whereas radiolarians are abundant above the OAE1d horizon. The mid-Cenomanian event (MCE) horizon is identified at the top of the Hikagenosawa Formation. Stepwise extinction of calcareous benthic foraminifers and a decrease in radiolarian diversity become apparent above the MCE horizon. In the study area, the OAE2 horizon has been well documented, and is placed in the middle part of the Saku Formation.

1. Introduction

Knowledge of Cretaceous ocean-climate systems provides important information to help understanding a future warm greenhouse world. In particular, the mid-Cretaceous warming around 120–90 Ma, enhanced by a huge production of oceanic crust and plateaus in the Pacific and Indian oceans, brought higher levels of greenhouse gases and high poleward heat transportation (e.g., Larson, 1991a,b). This global warming induced a unique deep-ocean circulation and expansion of anoxic conditions, known as oceanic anoxic events (OAEs) that resulted in large turnovers of marine biota (Leckie et al., 2002). Many palaeontological and geochemical studies of OAEs have been conducted in land sections across the Tethyan region (e.g., Erbacher et al., 1996), on deep-sea cores from the Atlantic (e.g., Bralower et al., 1994; Wilson and Norris, 2001), the Antarctic (e.g., Bralower et al., 1993), and from equatorial Pacific regions (e.g., Sliter, 1989), whereas there is little information about Cretaceous environmental events in the North Pacific.

The Cretaceous Yezo Group, exposed in central Hokkaido, northern Japan, was probably deposited at about 35–45°N (Hoshi and Takashima, 1999; Kodama et al., 2002) along a westward subduction margin in the north-eastern Asian continent during the Cretaceous. This group consists of a 10,000-m-thick forearc sedimentary sequence of sandstones and mudstones with subordinate conglomerates. This forearc basin is called the Yezo Basin (Okada, 1983), and it extends from offshore of north Honshu, through Hokkaido, to Sakhalin Island, Russia (Fig. 1). As the rocks contain abundant, well-preserved macro- and microfossils, many biostratigraphic schemes have been established (Matsumoto, 1942, 1977; Tanaka, 1963; Obata and Futakami, 1975; Futakami, 1982; Taketani, 1982; Maeda, 1986; Toshimitsu and Maiya, 1986; Motoyama et al., 1991; Kawabe et al., 1996, 2003; Takashima et al., 1997; Toshimitsu et al., 1998; Kawabe, 2000; Wani and Hirano, 2000; Moriya and Hirano, 2001; Ando et al., 2001; Nishi et al., 2003). In the last decade, carbon isotope excursions of organic materials have also been reported across the Cenomanian/Turonian boundary (OAE2) and from the upper Lower Aptian (Hasegawa and Saito, 1993; Hasegawa, 1995, 1997; Ando et al., 2002, 2003). Moreover, the thermal structure of the north-western Pacific of the Asian continental margin has recently been investigated, based on oxygen isotopic analyses (Moriya et al., 2003). These studies provide important information of Cretaceous environmental change and faunal turnover related to global events in the mid-latitude north-west Pacific.

However, the nomenclature of the lithostratigraphic divisions in the Yezo Group are complicated and differ between the areas investigated within Hokkaido, and several names have been used synonymously for the same lithostratigraphic unit. We, therefore, propose here a new, synthesized stratigraphic framework, including macro- and microfossil biostratigraphy, based on extensive mapping of the entire area in the central region of Hokkaido. Moreover, we organize the stratigraphic and geographic distribution of OAE horizons recorded in the Yezo Group using the new standard stratigraphy.

2. Geological setting

The Jurassic to Palaeogene sequences exposed in the western and central parts of Hokkaido, northern Japan, are basically divided into three N–S trending tectono-stratigraphic divisions called the Oshima (Cretaceous volcanic arc on a Jurassic accretionary complex), the Sorachi–Yezo (Cretaceous–Palaeogene forearc basin and accretionary complex), and the Hidaka (lower Palaeogene accretionary complex) belts from west to east (Kiminami et al., 1986; Ueda et al., 2000) (Fig. 1). These were formed along a westward-dipping subduction of the Izanagi–Kula plates under the eastern margin of the Asian continent (e.g., Okada, 1974).

The Sorachi–Yezo Belt consists of a coherent succession, from the Horokanai Ophiolite through the Sorachi Group to the Yezo Group (Fig. 2), and the accretionary complexes of the Idonnapu and Kamuikotan zones (Ueda et al., 2000; Fig. 1). The Horokanai Ophiolite and the lower part of the Sorachi Group represent a piece of basaltic oceanic crust (Ishizuka, 1981; Takashima et al., 2002a), while the upper part of the Sorachi Group is represented by subaqueous calc-alkaline and alkaline volcano-sedimentary sequences, suggesting an oceanic island arc setting (Girard et al., 1991; Niida, 1992; Takashima et al., 2002b). The Yezo Group conformably overlies the Sorachi Group and comprises very thick sandstone and mudstone sequences. The sand elastic of this sequence were derived from Cretaceous granitic rocks and Jurassic accretionary complexes of the Oshima Belt, which represents a contemporaneous continental arc setting (Kito et al., 1986). Although a part of the Hakobuchi Formation includes the upper Palaeocene in the Oyubari and Nakatonbetsu areas (Ando et al., 2001; Ando, 2003), the geological age of this formation ranges mostly from early Aptian to early Maastrichtian. Many hiatuses exist between the Campanian and Maastrichtian. The sedimentary environment of this group shows an eastward-deepening facies trend, from fluvial to continental slope (Fig. 2). The Yezo Group is unconformably capped by late Eocene, non-marine and shallow-marine sediments of the Ishikari and Poronai groups, or by younger Neogene deposits.
Fig. 1. Simple geological map showing the distribution of the Mesozoic formations of north-east Japan and southern Sakhalin. Dashed-lined frames show the study areas (Figs. 4, 5). The central region (Fig. 4) consists of the south-eastern Oyubari area and the north-western Mikasa area.
3. Stratigraphy of the Yezo Group

Lithostratigraphic nomenclature for the Yezo Group is very confused. Various definitions have been proposed, depending on the area and the researchers, because this group basically consists of a monotonous sequence of sandstone and mudstone and their alternating beds, which occasionally exhibit lateral facies changes. The criteria of lithological boundaries have been defined by sandstone intercalations and/or detailed changes of the sandstone/mudstone ratios in alternating beds. However, our study has revealed that the Yezo Group throughout Hokkaido is basically characterized by six alternations of mudstone-dominant units and sandstone-common units, with intercalations of six distinct stratigraphic key units (Fig. 2, Table 1). The revised lithostratigraphic definitions proposed in this paper are as follows, in ascending order (Figs. 2, 3): the Soashibetsugawa Formation (mudstone unit); the Shuparogawa Formation (sandstone-dominant turbidite unit); the Maruyama Formation (felsic tuff and tuffaceous sandstone unit); the Hikagenosawa Formation (mudstone-dominant unit); the Saku Formation (sandstone-common turbidite unit); the Kashima Formation (mudstone unit) and the Hakobuchi Formation (shallow-marine sandstone unit).

We also recognize the sandstone-dominant, outer-shelf to shoreface Mikasa Formation and the overlying, post- Yezo Group units, with evident changes in facies and sedimentary processes.

Fig. 2. Schematic diagram of the Yezo Group in the study areas. Note that the geological column shows eastward-deepening facies.

sandy mudstone-dominant outer-shelf Haborogawa Formation. The former is exposed in the Mikasa area, and the latter in the Tomamae and Mikasa areas (Figs. 2, 4, 5). The geological ages of these formations correspond to the Saku and Kashima formations exposed in the Oyubari area, respectively (Fig. 2). Additionally, in the study areas we name six stratigraphic key units as KY-1 to KY-6 consisting of olistostrome (KY-1), tuffaceous sandstone (KY-2, KY-4 to 6), and sandstone-conglomerate units (KY-3) (Fig. 2, Table 1).

3.1. Soashibetsugawa Formation (redefined)

**Definition.** This formation is characterized by a predominance of dark grey siliceous mudstone, and corresponds to the Soashibetsugawa Mudstone Member of the Shuparogawa Formation of Takashima et al. (2001) (Fig. 3). Takashima et al. (2001) defined the member as the basal unit of the Yezo Group because of the lithofacies shift from in situ volcanic and volcaniclastic rocks of the Sorachi Group to terrigenous, dark grey mudstone at the base of the member. As the member is widely traceable and clearly distinguishable from other members (sandstone-dominant facies) of the Shuparogawa Formation of Takashima et al. (2001), we redefine the member as the basal formation of the Yezo Group.

**Stratigraphic relationship.** This formation conformably overlies the Shirikishimanaigawa Formation of the Sorachi Group.

**Type section.** The Soashibetsu River section, northern Oyubari area (Figs. 4, 6; section 11).

**Lithology.** The formation consists of dark grey parallel-laminated mudstone with many intercalations of felsic tuff beds (Fig. 7A). The laminae are composed of felsic tuff and very fine-grained sand layers. Deep-sea trace-fossils, such as Lorenzinia and Cosmorhaphe, are found occasionally in the mudstone. The tuff beds are white, hard and generally 10–30 cm thick, though some beds attain a thickness of 1–7 m. They contain fine-grained, bubble-wall glass shards with minor amounts of idiomorphic feldspar and biotite.

**Thickness and distribution.** The formation is 450–700 m thick in the eastern part of the Oyubari area, and not exposed in the Mikasa and Tomamae areas.

**Fossils and age.** No macrofossils have been found in this formation. Radiolarians occur abundantly throughout the sequence of this formation, but there are no age-diagnostic species. Planktonic foraminifers appear rarely in the upper part (Fig. 8). The early Aptian species, Leupoldina cabri (Sigal), occurs from the uppermost part of the formation (Saito and Ando, 2000; Takashima et al., 2001; Nishi et al., 2003). Agglutinated benthic foraminifers, such as Bathysiphon, also occur occasionally.

**Depositional environment.** Microfossil assemblages and deep-sea trace fossils suggest an abyssal environment.

3.2. Shuparogawa Formation (redefined)

**Definition.** This formation, corresponding to the Tomitoi and Shuparogawa formations of Motoyama...
et al. (1991), is distinguished from the mudstone-dominant Soashibetsugawa Formation by the onset of common to frequent intercalations of sandstone beds.

**Type section.** Along the Shuparo River section, the central Oyubari area (Figs. 4, 6; section 12).

**Stratigraphic relationships.** The Shuparogawa Formation conformably overlies the Soashibetsugawa Formation in the Oyubari area, while the basal part of this formation is not exposed in the Tomamae and Mikasa areas because of poor exposure.

**Lithology.** The Shuparogawa Formation is mainly composed of alternating beds of turbiditic sandstone and dark grey mudstone. This formation incorporates a thick olistostrome bed (Kirigishiyama Olistostome Member) in the middle portion, and is subdivided into three members as follows: the Refureppu Sandstone, Kirigishiyama Olistostrome, and Okusakainosawa Sandstone and Mudstone members, in ascending order (Figs. 2, 6).

The Refureppu Sandstone Member consists of a very thick- to medium-bedded, sandstone-dominant sequence in the lower part (Fig. 7B) and thin to very thin-bedded, mudstone-dominant alternating beds in the upper part. It contains slump beds locally. Lower sandstones are stratified, well sorted, usually ranging from 10 to 50 cm thick, and occasionally more than 1 m thick. They are turbidites showing the S1–Tb-e divisions of Lowe (1982), with many sole marks. The sandstone/mudstone (S/M) ratio in the lower part is about 5/1. Sandstones in the upper part are less than 5 cm thick, with Tb-e divisions, and the S/M ratio is 1/2 to 1/5. Mudstones in this member are uniformly less than 10 cm thick, dark grey and weakly bioturbated. In the northern Oyubari area, this member is dominated by sandstone throughout (Fig. 6; section 11).

The Kirigishiyama Olistostrome Member represents an olistostrome bed containing huge allochthonous blocks of massive sandstone (<40 m thick), alternating beds of sandstone and mudstone (<20 m thick) and limestone (<60 m thick) in a muddy matrix (Fig. 7C). Limestone olistoliths consist of corals, large foraminifers (Orbitolina), rudists and ooids, contaminated with pebbles of chert, granite and sandstone. The width and thickness of limestone olistoliths is greatest in the northern Oyubari area where a 60-m-thick, slab-shaped block is continuously exposed for a distance of 3 km in a N–S direction (Fig. 4, around Mt. Kirigishiyama). The limestone olistoliths thin out in the Tomamae and southern Oyubari areas. However, the olistostrome bed is widely traceable throughout the study area as a key unit (KY-1) (Fig. 6).

The Okusakainosawa Sandstone and Mudstone Member basically comprises mudstone-dominant alternating beds, and varying thicknesses of sandstone, from 5 to 50 cm depending on the area (Fig. 7D). Sandstones are turbiditic, exhibiting Tb-e sequences with sole marks and numerous plant fragments, while thick sandstones show the S1–S3 divisions of Lowe (1982). In the Oyubari area, intercalations of sandstone become common to
abundant in the middle part of this member (Fig. 6; section 11). Mudstones are bioturbated with moderate numbers of trace fossils.

**Thickness.** The formation is approximately 1500 m thick in the type section. However, it varies in thicknesses, ranging from 800 to 2450 m.

**Fossils and age.** Mudstones of the Refureppu Sandstone Member yield a few foraminifers and common radiolarians, but no macrofossils (Fig. 8). Planktonic foraminifers include the Upper Aptian species, *Globigerinelloides barri* (Bolli, Loeblich and Tappan) and *G. duboisii* (Chevalier). Agglutinated and calcareous benthic foraminifers also occur occasionally. The Okusakainosawa Sandstone and Mudstone Member contains abundant radiolarians and planktonic foraminifers, with a subordinate proportion of common agglutinated and calcareous benthic foraminifers. The Upper Albian ammonoid, *Mortoniceras cf. geometricum* Spath, occurs in the upper part of this member (Kawabe, 2000). This member also includes the transitional interval from the *Ticinella primula* planktonic foraminifera (pf) Zone to the lower part of the *Biticinella breggiensis* pf Zone, assigned to the Lower—lower Upper Albian (Nishi et al., 2003) (Fig. 8). A significant hiatus is present from the *Planomalina cheniourensis* to *Hedbergella planispira* zones of Hardenbol et al. (1998), approximately 115.5—108.21 Ma (7 myr). It might have been eroded during deposition of the Kirigishiyama Olistostrome Member. The limestone olistoliths yield larger foraminifers of orbitolinds, e.g., *Orbitolina lenticularis* (Blumenbach), and its age is determined as Late Aptian—Early Albian (Matsumaru, 1971).

**Depositional environment.** Lithology and benthic foraminiferal data suggest that this formation was deposited on the continental slope (e.g., Motoyama et al., 1991). Benthic foraminifers of the Refureppu Sandstone Member and the Okusakainosawa Sandstone and Mudstone Member, consisting of species of *Bathytypus*, *Gaudryina*, *Gyroidinoides*, *Gavelinella* and *Nodosaria*, indicate the upper bathyal zone or deeper (e.g., Sliter and Baker, 1972). However, the limestones of the Kirigishiyama Olistostrome Member are considered to have been formed on a carbonate platform, such as a rimmed shelf along the Asian continental margin (Sano, 1995). The olistostrome indicates the collapse of the shallow carbonate platform and mixing with the bathyal mudstone around the Aptian/Albian boundary.

### 3.3. Maruyama Formation

**Definition.** This formation is defined by an assemblage of hard felsic volcanioclastic sandstones, tuffs and associated conglomerates (Motoyama et al., 1991) (Fig. 3). It also yields an excellent stratigraphic marker (KY-2), which extends throughout Hokkaido (Table 1).

**Type section.** Along the Shuparo River section, central Oyubari area (Figs. 4, 6; section 12).

**Stratigraphic relationship.** This formation conformably overlies the Shuparogawa Formation.

**Lithology.** This formation is composed of tuffaceous sandstone beds (Fig. 7E), locally accompanied by conglomerates at the base. The tuffaceous sandstone beds are 0.3—2 m thick, white to pale brown, siliceous and very hard. These beds have turbiditic features of graded to parallel-laminated sequences (Tb-e) and basal rip-up mudstone clasts. Microscopically, the sandstones are composed of platy glass shards, subordinate idiomorphic plagioclase, biotite, quartz and hornblende. The tuffaceous unit varies from 4 to 84 m thick throughout the study area.

The conglomerates accompanying the base of this formation are usually less than 2 m thick. However, in the central part of the Tomamae area (Fig. 5), the total thickness of the conglomeratic beds exceptionally attains as much as 900 m (Fig. 6; section 10). The conglomerates are thick-bedded, poorly sorted, and clast-supported, structureless or exhibiting R3—S1 divisions of Lowe (1982). The conglomerates consist mainly of subrounded pebbles—boulders of rhyolite, with subordinate, well-rounded granules to pebbles of mudstone, chert and siliceous mudstone in the Tomamae area, whereas in the Oyubari area they are composed of granules to pebbles of chert, sandstone, siliceous mudstone and limestone.

**Thickness.** This formation attains thicknesses of 180—900 m in the Tomamae area and 4—84 m in the Oyubari area. The horizon and thickness of this formation are disputable in the Mikasa area because of poor exposure.

**Fossils and age.** Although no planktonic foraminifers and macrofossils have been obtained from this formation, radiolarians (spumellarians) occur abundantly (Fig. 8).

---

Fig. 4. Geological map and structural profile section of the Oyubari and Mikasa areas, central Hokkaido Island region. The south-eastern Oyubari and north-western Mikasa areas are bounded by the Katsurazawa Thrust Fault. Although most areas in this map are based on our original data, the southern Mikasa area (the Manji and Hatonoisu domes) and northeastern Oyubari area (around the Mt. Yubaejama) are modified from Tanaka (1970), Obata and Futakami (1975), Futakami (1982) and Hashimoto (1953), respectively.
Fig. 5. Geological map and structural profile section of the Tomamae area; see Fig. 4 for legend.
Depositional environment. Abundant volcaniclastic materials in this formation suggest that huge, felsic volcanic eruptions episodically occurred along the western circum-Pacific/Asian continental margin. Main transporting channels for the volcanic sediments are inferred to have been located in the Tomamae area.

3.4. Hikagenosawa Formation

Definition. This formation is defined by the predominance of dark grey mudstone (Motoyama et al., 1991; Fig. 3), although there are intercalations of thin sandstone-dominant unit (Kanajiri Sandstone Member) in the lower middle part.

Type section. Along the Hikagenosawa Valley section, the central Oyubari area (Fig. 4).

Stratigraphic relationship. The formation overlies, conformably, the Maruyama Formation.

Lithology. The dominant lithology of the Hikagenosawa Formation is dark grey mudstone (Figs. 6, 7F). A thin unit of alternating beds of sandstone/conglomerate and mudstone (Kanajiri Sandstone Member) is intercalated in the lower middle part of this formation. This unit is used as a stratigraphic marker, the KY-3 (Fig. 2, Table 1).

The lower part of this formation is characterized by weakly-laminated mudstone. The intercalations of thin-bedded felsic tuffs and distal turbiditic sandstones showing Tc-e divisions are common in the Tomamae and Mikasa areas. In the northern Tomamae area, thick- to very thick-bedded sandstones with S1-S3 are exceptionally, also intercalated (Fig. 6; section 9). On the other hand, rare sandstones are intercalated in the Oyubari area. Mudstones in the upper part of this formation are moderately bioturbated, and occasionally weakly laminated.

The Kanajiri Sandstone Member is composed of thick- to very thick-bedded sandstone with very thick-bedded conglomerates in the Tomamae area, whereas in the Oyubari area it comprises thin- to medium-bedded, mudstone-dominant alternating beds of sandstone and mudstone (Fig. 7G). Sandstones are proximal (S3 in the former area and distal (T3 in the latter. The conglomerates are well-rounded pebbles to granules, exhibiting R3-S1 divisions. Their compositions are mostly chert with minor sandstone, mudstone and igneous rocks. The horizon and thickness of this member are disputable in the Mikasa area because of poor exposure and scarce fossil data.

Thickness and distribution. 1900–2600 m thick in the Oyubari area, and 1900–2000 m thick in the Tomamae area. The thickness in the Mikasa area is uncertain because of poor exposure.

Fossils and age. The occurrence of macrofossils (ammonoids and inoceramids) becomes common above the lower part of this formation (Fig. 8). The late Albian–middle Cenomanian ammonoids Mortoniceras rostratum (Sowerby), Mariella bergeri (Brongniart), Mantelliceras saxbii (Sharpe) and Cunnintoshicones cumingtoni (Sharpe) occur in the formation. Microfossils are abundant throughout the sequence. Exceptionally, planktonic foraminifers and calcareous benthic foraminifers are lacking around the Kanajiri Sandstone Member, whereas radiolarians become very abundant and agglutinated benthic foraminifers are common in this interval (Fig. 8). Planktonic foraminifers indicative of the Biticinella breffensis to Rotalipora cushmani pf zones, for example, Biticinella breffensis (Gandolfi), Ticinella subticinensis (Gandolfi), Rotalipora appenninica (Renz), R. globotruncanoides Sigal, and R. cushmani (Morrow), occur, indicating a Late Albian–Late Cenomanian age (Nishi et al., 2003; Fig. 8).

Depositional environment. Benthic foraminiferal assemblages suggest that this formation was deposited in the lower part of the upper bathyal zone under relatively oxygenated conditions (Motoyama et al., 1991; Kaiho et al., 1993).

3.5. Saku Formation

Definition. This formation is defined by the frequent intercalations of turbiditic sandstone beds (Matsumoto, 1942).

Type section. The Abeshinai River section, Teshionakagawa area, northern Hokkaido (Fig. 1). The lithology and distribution of this formation were well documented by Matsumoto (1942) and Matsumoto and Okada (1973).

Stratigraphic relationship. The formation overlies conformably the Hikagenosawa Formation.
Lithology. This formation comprises alternating beds of turbiditic sandstone and mudstone, and intercalates with a unit characterized by a predominance of greenishgrey muddy sandstones (Hakkin Muddy Sandstone Member; KY-4) in the middle part (Fig. 2, Table 1).

Sandstones in the lower part (below the KY-4) are less than 40 cm thick and exhibit typical turbiditic sequences, having $T_{b-e}$ divisions. Mudstones are dark grey-coloured and moderately bioturbated. The S/M ratios change from 1/10 to 1/1 (Fig. 7H).

A very characteristic lithofacies, greenish grey muddy sandstone with abundant trace fossils of Planolites (Fig. 7I), is observable in the middle part of this formation. This greenish unit extends from the Oyubari area to the central Tomamae area, about 200 km, and is defined as the KY-4 (Hakkin Muddy Sandstone Member). The member incorporates medium-/thick-bedded sandstones, with $S_2-T_{b-e}$ divisions, and frequent felsic tuff beds. The tuff beds vary in thickness from 0.02 to 2 m, and are altered to bentonites. Finely laminated, pyrite-rich, dark grey—greyish black mudstones are intercalated just below or in the lower part of this member in the Oyubari and Tomamae areas.

The upper part of the formation begins with dark grey mudstone and changes to alternating beds of sandstone and mudstone. Sandstones are thin- to medium-bedded turbidites with $T_{b-e}$ sequences, and the S/M ratios are not high, 1/10 to 1/5. Slump beds and sandstone dykes are common in the southern Oyubari area. Sandstones are occasionally intensively bioturbated and bedding planes of some beds are destroyed. Mudstones and sandy mudstones are dark grey to grey and intensively bioturbated.

On the other hand, the Saku Formation, exposed in the northern Tomamae area, is marked by four thickening-upward sequences (Fig. 6; section 8). A channel-filling conglomerate/sandstone unit constitutes the first and third sequences. The conglomerates are clast-supported, and 0.5—4 m thick, with disorganized erosional bases (Fig. 7J). Graded bedding, from well-rounded cobble to coarse sandstone ($R_{2,3}$—$S_1$ divisions), is common. The sandstones are very thick-/thick-bedded, showing $S_1-T_{b-e}$ divisions. The second and fourth cycles show the facies changes from very thick-/thick-bedded, sandstone-dominant alternating beds to thin-bedded mudstone-dominant ones. The sandstones are proximal turbidites, exhibiting $S_1-T_{b-e}$ divisions.

Thickness and distribution. 2300 m in the Oyubari area, 1800—2000 m in the Tomamae area. The upper part of this formation is truncated by the N—S trending thrust fault (Kashima Thrust Fault) in the northern Oyubari area (Fig. 4).

Fossils and age. Except for the Hakkin Muddy Sandstone Member the formation contains abundant macrofossils (Fig. 8). The Cenomanian ammonoids, Calycoceras spp., occur in the lower part of the formation. The blackish-grey mudstone intercalated in the basal part of the Hakkin Muddy Sandstone Member is correlated with the Cenomanian/Turonian boundary, based on the results of carbon isotope, mega- and microfossil stratigraphy (e.g., Hasegawa and Saito, 1993; Hirano, 1995). Although macrofossils are few in the Hakkin Muddy Sandstone Member, Lower Turonian indicators, such as Pseudaspidoeceras flexuosus (Powell) and vascoceratids, occur. The upper sequence is marked by an abundant occurrence of heteromorphic ammonoids, including Nippontites, Eubostrichoceras and scaphitids, with minor Middle Turonian indicators, such as Romaniceras spp. (ammonoid) and Inoceramus hobetsensis Nagao and Matsumoto (bivalve). Microfossils commonly occur throughout the sequence; radiolarians are especially abundant in the Hakkin Muddy Sandstone Member, and occupy 80—90% of the total. This formation ranges from the Rotalia pora cushmani to Helvetoglobotruncana helvetica pf zones, assigned to the Upper Cenomanian—Middle Turonian (Nishi et al., 2003; Fig. 8).

Depositional environment. The benthic foraminiferal assemblages indicate the lower part of upper
Fig. 7 (continued)
bathyal depth-zone with relatively low-oxygen conditions (Kaiho et al., 1993).

### 3.6. Mikasa Formation

**Definition.** This formation is the contemporaneous, shallower facies of the Saku Formation, and is defined by the predominance of sandstones exhibiting hummocky and trough cross-stratification (Matsumoto, 1951; Ando, 1990a).

**Type section.** North-west of Katsurazawa Lake, in the eastern Mikasa area (Fig. 4).

**Lithology.** The Mikasa Formation is characterized by a predominance of sandstones with hummocky and trough cross-stratification (HCS and TCS) and gravel/shell lags, and intensively bioturbated sandy mudstone (Fig. 7K). It is divided into three coarsening-upward successions, assigned as third-order depositional sequences (DS$_1$, DS$_2$ and DS$_3$), each of which further includes three fourth-order sequences (4th DS) (Ando, 1997).
Within each DS, conglomerate and coarse-grained sandstone tend to thicken in the west, and interbedded sandy mudstone becomes dominant and thick in the east.

In the northwestern Mikasa area, the DS₁ begins with alternating beds of turbiditic sandstone and mudstone, and grades into HCS sandstone with bioturbated, very fine-grained sandstone/sandy mudstone. A basal thick, cross-stratified conglomerate of the DS₂ covers HCS sandstones of DS₁ with a sharp erosional base (unconformity) (Fig. 6; section 2). The DS₂ comprises a wide variety of lithofacies, such as cross-stratified conglomerate, carbonaceous mudstone, sandy mudstone with oyster-shell beds, medium- to coarse-grained sandstone with TCS, HCS fine sandstone and bioturbated sandy mudstone. The DS₃ deposits are distributed in the southern Mikasa area, mainly comprising bioturbated, sandy mudstone and HCS sandstones. The intercalations of HCS sandstone become frequent in the upper part of each fourth DS. These DSs grade into the Saku Formation northward and eastward.

Thickness and distribution. This formation is exposed only in the Mikasa area, forming the Sorachi–Ikushumbetsu Anticline and the Manji and Hatonosu domes. Its thickness ranges from 400 to 750 m, and it tends to thicken eastward.

Fossils and age. Shallow-marine bivalves (including Aiptotrigonia, Glycymeris, Meekia, Pinna, Pseudoptera, Pterotrigonia, Thetis, Yaadia), gastropods (e.g., Margarites, Semisolarium) occur as storm-lag deposits within HCS sandstones. Bioturbated, muddy sandstones to sandy mudstones contain rare to common ammonoids and inoceramids, but no microfossils. The Cenomanian ammonoids, Mantelliceras sp., Calycoceras sp. and Desmoceras spp. have been reported from the DS₁ deposits (Kawabe, 2003). The Turonian species, Inoceramus hobetsensis and Inoceramus teshioensis Nagao and Matsumoto, are abundant in the Oyubari area. The thickness of the mudstones is variable, depending on the area, but all are less than 2 m thick. A diagnostic feature of this unit is abundant occurrences of Inoceramus uwajimensis Yehara from the interbedded mudstone (Fig. 7M). This unit is an excellent stratigraphic marker (KY-5) throughout the study areas (Table 1).

Compared with the lower unit, the upper volcanioclastic unit differs in lacking mudstone intercalations and macrofossils. Tuffaceous sandstones or tuffs are thick-bedded (<1 m thick), white, coarse- to very fine-grained. Some are altered to bentonite.

Thickness. About 1670 m in the southern Oyubari area. The thickness of this formation in the northern Oyubari area is difficult to estimate because of the monotonous lithology and complex geological structure, with isoclinal folding and thrust faulting.

Fossils and age. This formation contains abundant calcareous concretions, including macrofossils such as ammonoids and inoceramids. I. uwajimensis is particularly abundant in the KY-5 unit (Fig. 8).

Microfossils (foraminifers and radiolarians) are abundant, although Tethyan marker-species are very rare. The following four mid-latitude zones of planktonic foraminifers have, therefore, been proposed from the Late Turonian to Campanian in the study area, namely: the Marginotruncana pseudolineatana, M. sinuosa, Contusotruncana fornicata, and Globotruncana arca pf zones (Fig. 8). These can be correlated directly with...
the Tethyan planktonic foraminiferal zones (Nishi et al., 2003).

Depositional environment. The benthic foraminiferal assemblages indicate the upper part of the upper bathyal environment with medium- to relatively high-oxygen levels (Kaiho et al., 1993).

3.8. Haborogawa Formation (new)

Definition. The base of this formation is delineated by bioturbated mudstone without sandstone intercalations, overlying the Saku Formation. While the lower part of this formation is mainly composed of bioturbated mudstone, the upper part is characterized by coarsening upward successions, from mudstone to muddy sandstone and/or sandstone.

Type section. The Nakafutamata River section, in the northern Tomamae area (Figs. 5, 6; section 7).

Stratigraphic relationships. The formation is exposed in the Tomamae and Mikasa areas, and conformably overlies the Saku and Mikasa formations, respectively. It is the synchronous shallower-water facies of the Kashima Formation.

Lithology. The lithology and sedimentary cycles of this formation differ between the Tomamae and Mikasa areas. In the Mikasa area the formation forms a single, coarsening-upwards sequence, from bioturbated sandy mudstone to very fine-grained sandstone. Two felsic volcaniclastic turbidite units of the KY-5 and KY-6 (Tsukimi Sandstone Member) are intercalated in the lower and middle parts, respectively. The KY-5 unit consists of thick beds of volcaniclastic sandstones with abundant Inoceramus uwajimensis. In the Tsukimi-sawa Valley section, the KY-5 becomes channel-fill conglomerates, including well-rounded pebbles of chert, sandstone and mudstones and rhyolitic rocks, with abundant fragments of I. uwajimensis. They are high-density turbidite beds, exhibiting the S1-2 divisions of Lowe (1982). The KY-6 unit (Tsukimi Sandstone Member) is 20 m thick and exposed in the eastern Mikasa area. This unit consists mostly of volcaniclastic sandstones with very thin interbedding of dark grey mudstones. The sandstone beds range from 0.2–2 m thick, and display the S1–Tb-e divisions of Lowe (1982) (Fig. 7N).

In the Tomamae area, this formation consists of two coarsening-upwards sequences. Both begin with strongly bioturbated mudstone, grade into bioturbated muddy sandstone, and end in medium- to coarse-grained, cross-laminated sandstone (Fig. 7O). The lower coarsening-upward sequence incorporates the volcaniclastic marker unit of the KY-5 in the lower part and the KY-6 at the top, respectively.

Thickness. Approximately 1950 m in the Mikasa area, 1750–2250 m in the Tomamae area.

Fossils and age. This formation yields abundant, well-preserved macrofossils from calcareous concretions in both the Tomamae and Mikasa areas (e.g., Futakami, 1986; Maeda, 1986; Wani, 2001; Moriya et al., 2003). Several regional biozones, the I. uwajimensis-I. mihoensis, I. amakusensis, and I. japonicus inoceramid zones, have been proposed in the Tomamae area by Toshimitsu and Maiya (1986). Microfossils are abundant throughout the study areas. Although Tethyan planktonic foraminifers are sporadic, the four mid-latitude zones, from the Marginotruncana pseudolineeiana to the Globotruncan arca pf zones, can be identified in this formation. Its geological age is considered to be Coniacian—Campanian (Moriya et al., 2001; Nishi et al., 2003; Fig. 8).

Depositional environment. The mudstone in the northern Tomamae area contains abundant benthic foraminifers, e.g., Gavelinella, Gyroidinoideas, Hoeglundina, Oolina, and Silicosigmoilina. The palaeodepth of this assemblage is considered to be outer shelf (Sliter and Baker, 1972). The cross-stratified sandstone situated towards the top of each succession (i.e., KY-6) in the northern Tomamae area is inferred to have been deposited in inner shelf to lower shoreface environments (Toshimitsu, 1985; Wani, 2003).

3.9. Hakobuchi Formation (new)

Definition. This formation is defined by the predominance of HCS and TCS sandstones and conglomerates, and corresponds to the Hakobuchi Group of Matsumoto (1942).

Type section. Downstream of the Shuparo River (dam site of Lake Shuparo) in the Oyubari area (Figs. 4, 6; section 15).

Stratigraphic relationships. This formation conformably overlies the Kashima Formation in the Oyubari area and the Haborogawa Formation in the north-eastern Mikasa and Tomamae areas. However, the unconformable relationship between the Haborogawa and Hakobuchi formations is recognized in the north-western limb of the Sorachi Anticline, north-western Mikasa area. The Hakobuchi Formation is overlain by a disconformity, or an angular unconformity, and is covered by deposits younger than the Paleocene, such as the middle–upper Eocene Ishikari Group, containing coal measures, or the upper Eocene–lower Oligocene offshore-marine Poronai Group.

Lithology. As the deposits of the Hakobuchi Formation form complicated stacking patterns of the
third- and fourth-order depositional sequences (DSs), the lithology varies depending on areas and horizons, as for the Mikasa Formation (Ando, 2003). The number of sequences differs between sections, but the maximum reaches over 15, including third- and fourth-order DSs. They mainly consist of coarsening-upwards facies successions (CUS), a few tens to 100 m thick, of bioturbated sandy mudstone to HCS/TCS sandstone (Fig. 7P). Often, there is an associated thin, fining-upwards marine succession (FUS), not more than a few metres thick, below the CUS. Fluvial conglomerate, sandstone, mudstone and sometimes coaly beds are intercalated in the basal part of the DSs. Thick marine conglomerates and fluvial-channel conglomerates are subordinately developed at several horizons. Felsic tuffs are interbedded at a few horizons, and thicken in the northern Mikasa and northern Tomamae areas, where the beds attain 30 and 80 m in thickness, respectively. Compared with the Mikasa Formation, the Hakobuchi Formation is characterized by a smaller amount of offshore mudstone and a larger amount of conglomerate and tuff.

**Thickness and distribution.** The thickness is variable, ranging from several tens to 450 m thick in the Mikasa and Oyubari areas (Ando, 1997). The formation is 250 m thick in the northernmost part of the Tomamae area.

**Fossils and age.** Although a few macrofossils, such as *Sphenoceras schmidtii* (Michael), *S. hetonai anus* (Matsumoto), and *Inoceramus shikotanensis* Nagao and Matsumoto, occur in this formation (Ando, 1997; Ando et al., 2001), there are no age-diagnostic species. The planktonic foraminifers *Globotruncana rugosa* (Marie) and *Subbotina triloculinoides* (Plummer) occur in the lower and upper parts of this formation, respectively (Yasuda, 1986). The former is assigned to the Campanian (Robaszynski et al., 1984), and the latter is of Paleocene age (Yasuda, 1986). The Cretaceous/Palaeogene boundary sequence has not been detected in the Hakobuchi Formation.

**Depositional environment.** Depending upon the stratigraphic position within the third- or fourth-order DSs, the depositional environments represented change regularly and repetitively. They include shallow-marine environments, such as outer to inner shelf and shoreface, and subordinately estuarine, incised valley, and riverine gravelly/sandy river-channel, back-marsh and floodplain.

### 4. Lateral change of depositional environments in the Yezo Basin

The Yezo Group is lithologically characterized by an alternating sequence of turbidite-dominant and hemipelagic mudstone-dominant units (Fig. 2). The Aptian–Albian sequences are laterally similar in all study areas, comprising the laminated mudstone Soa-shibetsugawa Formation, the turbiditic Shuparogawa and Maruyama formations, and the mudstone Hikage-nosawa Formation, in ascending order. Sedimentary structures, lithological associations and sedimentary sequences show slope fan with channel-fill structures. Scarce occurrences of macrofossils, and common occurrences of deep-sea trace fossils, suggest abyssal environments in the Aptian. Benthic foraminifers indicate the upper bathyal zone, about 300–600 m in depth, in the Albian.

The Cenomanian–lower Campanian rocks display lateral variations in lithology, tending to north-westward coarsening and shallowing sequences (Fig. 2). The uppermost Albian–Turonian Mikasa Formation is typically composed of shallow-marine, including fluvial, estuarine and outer-shelf, sediments, suggesting rapid uplift in the western margin of the Yezo Forearc Basin. The overlying Haborogawa Formation represents deeper facies than the Mikasa Formation in terms of sedimentary environment, as indicated by the occurrence of shoreface to outer shelf, and partly upper bathyal basin-plain deposits. On the other hand, the Cenomanian–Turonian Saku Formation and Coniacian–Campanian Kashima Formation exhibit slope fan on continental slope and basin-plain successions, respectively. Based on benthic foraminiferal assemblages, these formations were deposited in upper bathyal depths.

The neritic to non-marine Hakobuchi Formation, deposited during the Campanian–Early Maastrichtian and Late Paleocene interval, completely covers the deep-sea sediments across the whole area from north to south. This formation indicates the final stage of deposition and uplift of the Yezo Forearc Basin.

### 5. OAE horizons in the Yezo Group

Laminated, organic-rich marine sediments, indicating six oceanic anoxic events (OAEs 1a–1d, 2 and the mid-Cenomanian Event, MCE) have been reported from mid-Cretaceous deep-sea cores and land sections in the European Basin, North and South Atlantic oceans, and equatorial mid-Pacific mountains and plateaus (e.g., Erbacher et al., 1996; Leckie et al., 2002; Coccioni and Galeotti, 2003). These sediments are visually-distinctive, so-called “black shales”, found as black to dark grey intercalations in white, pelagic limestones or grey marlsstones. These black shale intervals commonly consist mainly of finely alternating layers of calcareous fossil-rich laminae and clay/organic matter (Arthur and Sageman, 1994).

However, terrigenous, siliciclastic sequences exposed in the North Pacific regions, such as the Yezo Group in
Japan, are generally composed of dark grey mudstones and pale grey sandstones. Dark grey, monotonously-coloured deposits throughout the successions prevent visual recognition of OAE levels in background sediments in certain outcrops. In the Yezo Group, the average total organic carbon (TOC) content is about 0.5–1.2 wt% (Hasegawa and Saito, 1993), higher than those in the Tethyan and Atlantic carbonate rocks and marlstones (usually TOC is less than 0.5 wt%). The organic matter is mostly derived from terrestrial plants throughout the sequences, suggesting that organic fragments (origin of the TOC) were transported from the westward Asian continental margin. Therefore, as the TOC of the Yezo Group is not a useful indicator of anoxic environments, the biostratigraphy and chemostratigraphy are both very important in identifying OAE horizons in this sequence. Several chemostratigraphic studies, using organic carbon isotopes from the Saku Formation, have reported a positive $\delta^{13}$C$_{org}$ excursion record related to the global burial event of marine organic matter around the Cenomanian/Turonian boundary (OAE2; Hasegawa and Saito, 1993; Hasegawa, 1995, 1997; Hasegawa and Hatsugai, 2000). Moreover, another positive $\delta^{13}$C$_{org}$ excursion (ca. 3.6‰) was observed in the Soashibetsugawa Formation of the northern part of the Oyubari area (OAE1a; Ando et al., 2002, 2003). Here we summarize the published biostratigraphic and chemostratigraphic results of the study areas using the new stratigraphic classification presented in this paper (Fig. 8), and identify and describe the OAE horizons in the sequence.

5.1. OAE1a horizon

The late Early Aptian OAE1a, spanning about 1 myr (119.5–120.5 Ma; Larson and Erba, 1999), named as the Niveau Goguel in the Vocontian Basin of France, Livello Selli in Italy and Fischschiefer in Germany, is a global, organic-carbon burial-event. This OAE occurred within the basal part of the Leupoldina cabri pf Zone (Premoli-Silva et al., 1999). There was a microfossil (planktonic foraminiferan and radiolarian) diversity decrease, and nannoconid (calcareous nannoplankton) species disappeared around the OAE1a event (Erba, 1994; Premoli-Silva et al., 1999). The sharp negative $\delta^{13}$C$_{carbonate}$ excursion (0.5–3‰), and the following abrupt, prolonged positive one (>2‰), are recorded in this event (Menegatti et al., 1998).

In the Yezo Group, a pair of negative and positive $\delta^{13}$C$_{org}$ excursions have been found in the Soashibetsugawa Formation of the Sorachi Group in the Oyubari area (Ando et al., 2002, 2003). This formation has been redefined as the Soashibetsugawa Formation of the Yezo Group, as described above. Because the paired excursion spikes occur near the first appearance datum (FAD) of Leupoldina cabri, this positive excursion correlates with the OAE1a event (Fig. 8). The OAE1a interval in the study area is very thick, about 110 m (Fig. 6; section 11), compared with 1–5 m in the Italian and Swiss sections (Menegatti et al., 1998). The extraordinarily thick interval in the Yezo Group resulted from a huge terrestrial influx from the active Asian continental margin. Mudstone in this interval is characterized by rare bioturbation and fine laminations, with scarce or no benthic macro- and microfaunas.

5.2. OAE1b horizon

OAE1b was a long-lived event, extending from the Ticinella bejaouaensis to Hedbergella planispira pf zones (114.5–108.21 Ma, about 6.3 myr; Hardenbol et al., 1998). This event is represented by several black shales: (1) the uppermost Aptian Niveau Jacob in the Vocontian Basin and Livello “113” in central Italy, and (2) the lower Albian Niveau Kilian, Paquier and Leenhardt in the Vocontian Basin, and Livellos Monte Nerone and Urbino in the Apennines of central Italy.

In the Yezo Group, an interval spanning the T. bejaouaensis to H. planispira pf zones was not detected, because the interval is placed within the olistostome bed (Fig. 8). Consequently, OAE1b is missing owing to erosion or hiatus by a tectonic event in the study area.

5.3. OAE1c horizon

Black shales representing the OAE1c event are characterized by abundant terrigenous organic matter in the lower Upper Albian Biticinella breggiensis pf Zone in central Italy (Amadeus Level) (Erbacher et al., 1996). The $\delta^{13}$C$_{carbonate}$ excursions within the B. breggiensis pf Zone are not distinct in the Italian section (Erbacher et al., 1996), whereas a prominent negative excursion of $\delta^{13}$C$_{org}$ (1.5‰) has been identified in the Santa Rosa section, Mexico (Bralower et al., 1999).

In the Yezo Group, the B. breggiensis pf Zone spans the uppermost part of the Shuparogawa Formation to the basal part of the Hikagenosawa Formation (Fig. 8), and is 300 m thick. A negative $\delta^{13}$C$_{org}$ excursion of about 1‰ occurs at the top of the Shuparogawa Formation (Hirano and Fukuj, 1997), and is followed by a radiolarian high-productivity event in the Maruyama Formation (Fig. 8). This excursion interval could be correlateable with the OAE1c horizon of Leckie et al. (2002).

5.4. OAE1d horizon

The uppermost Albian black shales (OAE1d, Breistroffer Level) occur in the upper part of the Rotalipora appenninica pf Zone, as well as in the Stoliczkaia dispar ammonite Zone, in Tethyan–Atlantic regions (Gale et al., 1996; Wilson and Norris, 2001). Broad positive excursions of $\delta^{13}$C$_{carbonate}$ within this interval suggest
globally significant organic-carbon burial (Erbacher et al., 1996; Gale et al., 1996; Nederbragt et al., 2001; Wilson and Norris, 2001). The OAE1d horizon in the equatorial Atlantic region is marked by a collapse of upper water-column stratification due to intensified winter mixing and reduced summer stratification (Wilson and Norris, 2001). Biological records indicate that this OAE event damaged planktonic foraminiferal and radiolarian populations, as well as the carbonate platforms (Erbacher et al., 1996; Nederbragt et al., 2001).

In the Yezo Group, the R. appeninnica pf Zone is correlatable with the lower middle part of the Hikagenosawa Formation (Fig. 8). Although the base of the R. appeninnica pf Zone is indefinite because of the presence of a thick interval of rare to barren planktonic foraminifers, mudstones in the lower part of this formation contain the upper Albian ammonoids Mortoniceras, Dicarinella rostratum and Mariella bergeri (Kawabe et al., 2003; Fig. 8). These ammonoids are index species of the upper Albian Stoliczkaia dispar ammonite Zone, as well as the R. appeninnica pf Zone, in Tethyan biozonations. A broad, positive excursion of the δ13Corg, which is similar to the δ13Ccarbonate curve of OAE1d in the Tethyan–Atlantic region, is observed in the lower part of the Hikagenosawa Formation, just below the Kanajiri Sandstone Member (KY-3) of the Yezo Group (Hirano and Fukuju, 1997; Fig. 8). This horizon is located within the upper part of the Stoliczkaia dispar ammonite Chronozone (Kawabe et al., 2003). Hence, we concluded that this excursion level is correlatable with OAE1d.

The rocks correlated to the OAE1d interval are weakly-laminated and pyrite-rich mudstones. Planktonic foraminifers are very rare to absent, whereas spumellarian radiolarians suddenly increased in abundance. Agglutinated benthic foraminifers are common, with assemblages of Bathysiphon, Glomospira and Haplophragmoides, and rare Gyroidinoides and Lenticulina. The dominance of agglutinated forms might reflect relatively dysoxic conditions, as well as the Cenomanian/Turonian boundary (Kaiho and Hasegawa, 1994). Although a dissolution effect on calcareous species cannot be ruled out, our results suggest that dysoxic conditions developed and a radiolarian high-productivity event took place during the OAE1d in the north-west Pacific.

5.5. The mid-Cenomanian Event horizon

The mid-Cenomanian Event (MCE) is a major turnover of foraminifers and radiolarians associated with a 0.7‰ positive shift in δ13Ccarbonate and a positive shift in the Sr/Ca ratio (Coccioni and Galeotti, 2003). The organic-rich layers corresponding to this event have been found in central Italy, the Vocontian Basin (Coccioni and Galeotti, 2003), and the North Atlantic (Deep Sea Drilling Project Sites 367, 386 and 398; Cool, 1982; Arthur and Dean, 1986; Summerhayes, 1987). In central Italy, this event is associated with upper Cenomanian organic-rich layers up to the Cenomanian/Turonian boundary. The MCE level shows a global positive excursion in carbon isotope records, correlatable within the middle part of the Dicarinella algeriana pf Subzone of the Rotalipora cushmani pf Zone. Above this event, radiolarian and benthic foraminifers decrease in diversity in central Italy (Erbacher et al., 1996; Damesté and Köster, 1998; Coccioni and Galeotti, 2003).

Hasegawa (1997) proved a sudden positive excursion of δ13Corg (about 1.2‰) within KS19a (= the D. algeriana pf Subzone) in the Hakkin-zawa River (Shirokin River in Hasegawa, 1997) section of the Oyubari area. This positive peak is probably correlatable with the MCE horizon in central Italy. Therefore, the horizon is placed at the top of the Hikagenosawa Formation of our lithostratigraphic division. Benthic foraminiferous assemblages show a stepwise extinction, marked by a 43% reduction of calcareous species during the 3 myr after the MCE event in the southern Oyubari area (Kaiho and Hasegawa, 1994; Fig. 8). Radiolarian abundances decrease during the same interval (Taketani, 1982).

5.6. OAE2 horizon

OAE2 (the Bonarelli Event) was the largest environmental and biotic disturbance during the mid-Cretaceous interval. Major phenomena include maximum mixed-layer temperatures (about 33–34 °C; Wilson et al., 2002), an abrupt drop in 87Sr/86Sr isotopic values (Bralower et al., 1997), increased volcanic deposits and intensive hydrothermal activity (Sinton and Duncan, 1997). This event is marked by a positive excursion of δ13Ccarbonate (>2‰) within the Whiteinella archaeoectaceae pf Zone, close to the Cenomanian/Turonian (C/T) boundary, and is considered to be related to increased productivity and global expansion of the oxygen minimum zone (e.g., Damesté and Köster, 1998; Premoli-Silva et al., 1999). A significant turnover of radiolarians, calcareous nannofossils, and deep-dwelling planktonic foraminifers occurred, with a high extinction rate (26% of all genera) of benthic foraminifers (Erbacher et al., 1996; Erbacher and Thurow, 1997; Premoli-Silva et al., 1999).

The C/T boundary, based on macro- and microfossil biostratigraphy, is placed at the base of the Hakkin Muddy Sandstone Member of the Saku Formation in the Oyubari and Tomamae areas (Figs. 4, 6; sections 10, 13, and 14). A positive δ13Corg excursion of about 2.5‰ is recorded at this boundary, indicating OAE2 (e.g., Hasegawa and Saito, 1993). Investigation of benthic foraminiferous assemblages in the Oyubari area demonstrates that the two lowest oxygen conditions developed during 0.15 myr before the C/T boundary and 1.5 myr after (Kaiho and Hasegawa, 1994). Radiolarians
become abundant just above the C/T boundary (e.g., Hasegawa, 1997; Fig. 8).

6. Conclusions

Our study of the Yezo Group, a thick, forearc basin-fill sequence, distributed across Hokkaido, Japan, serves as an important record of tectonic, faunal and environmental change on the north-west Pacific margin during the Cretaceous Period. The litho- and biostratigraphic summaries of the sequence were previously little known, and various lithostratigraphic divisions had been proposed. Based on our wide areal mapping of the sequences, as well as analyses of litho- and biofacies, we have here proposed a new lithostratigraphic scheme for the sequence.

The Aptian–Albian sequences (the Soashibetsugawa, Shuparogawa, Maruyama and lower Hikagenosawa formations) of the group were deposited on a continental slope with a lower–upper bathyal palaeodepth in all sections. The Cenomanian to lower Campanian sequences exhibit lateral variations of sedimentary environment in the study areas. Generally, the sequences exposed in the Mikasa and Tomamae areas show shallower facies of shelf to non-marine environments (the Mikasa and Haborogawa formations), while those in the Oyubari area represent continental slope environments (the upper Hikagenosawa, Saku and Kashima formations). Above the lower Campanian, the neritic to non-marine facies of the Hakobuchi Formation were deposited in all areas.

The sequence does not contain intercalated black shales, as seen in the Tethyan and Atlantic regions, because of rapid sedimentation and a constant voluminous influx of terrigenous detritus. However, the integration of the bio- and chemostratigraphic results of the study areas, using our new stratigraphic scheme, reveals the OAE1a, 1c, 1d, MCE and OAE2 horizons in the Yezo Group. The OAE1a, 1c, 1d and 2 horizons are characterized by a lack of calcareous foraminifers; instead, they are closely accompanied by a radiolarian high-productivity event. On the other hand, the MCE horizon corresponds to the onset of a decrease in radiolarian abundance and stepwise extinction of calcareous benthic foraminifers.

Acknowledgements

We express sincere gratitude to Y. Takayanagi, T. Saito (Tohoku University), H. Hirano (Waseda University), S. Sano (Fukui Prefectural Dinosaur Museum), T. Tomosugi (Kyushu University), and K. Kurihara (Mikasa City Museum) for helpful suggestions, and also to K. Kobayashi, K. Hasegawa, S. Matsuda, K. Matsuda, N. Watanabe, K. Komoto (Mikasa City) for support during our fieldwork. We thank T. Hatsugai, A. Ennyu, S. Egawa, F. Suzuki, A. Ando and T. Sakai for provision of unpublished data. This study was supported financially by the JSPS Research Fellows Scheme (No. 09898 to Takashima, No. 06365 to Wani, and No. 07622 to Moriya), Grants-in-Aid from JSPS (No. 14740302 to Kawabe, No. 10640446 to Ando, and Nos. 13354006 and 15340176 to Nishi), and in part by a 21st Century Center of Excellence (COE) Program on “Neo-Science of Natural History” at Hokkaido University.
